Abstract

Graphene and topological insulators (TI) possess two-dimensional (2D) Dirac fermions with distinct physical properties. Integrating these two Dirac materials in a single device creates interesting opportunities for exploring new physics of interacting massless Dirac fermions. Here we report on a practical route to experimental fabrication of graphene-Sb₂Te₃ heterostructure. The graphene-TI heterostructures are prepared by using a dry transfer of chemical-vapor-deposition grown graphene film. ARPES measurements confirm the coexistence of topological surface states of Sb₂Te₃ and Dirac π bands of graphene, and identify the twist angle in the graphene-TI heterostructure. The results suggest a potential tunable electronic platform in which two different Dirac low-energy states dominate the transport behavior.

Dirac materials such as graphene and topological insulators (TI) have been in the spotlight attracting global research interest in the past decade, because they not only provide unprecedented opportunities to explore fundamental physics in condensed matters but also open a new route for device innovations thanks to the unique electronic properties of those materials.[1–9] In both graphene and TIs, the low-energy excitations can be described as a two dimensional (2D) electron gas with linear dispersion akin to massless Dirac fermions. There is a key difference between the two systems: in graphene the intrinsic spin-orbit coupling (SOC) is negligibly small and the chirality of the Dirac state is associated with the sublattice degrees freedom, the so-called pseudospin; on the other hand, in TIs the topological bulk band ordering is caused by the strong SOC and gives rise to the helical spin-momentum locked feature of the Dirac surface states. There have emerged many interesting proposals of combining the two Dirac materials in heterostructures, taking advantage of the dramatic difference in spin texture of their Dirac states.[10–14] It has been predicted that the SOC of graphene can be greatly enhanced by proximity to the strongly spin-orbit coupled TI surface. As a consequence, the epitaxial graphene can develop a spin-orbit gap as large as 20 meV, making it a Kane-Mele quantum spin-Hall insulator.[12, 15] Thus the major interest in this type of heterojunctions is the potential for engineering electronic structure of graphene by proximity effect. Despite several experimental efforts to grow TI films on graphene substrate[16–18] the experimental fabrication of a graphene layer on top of TI surface remains a tremendous technical challenge, not to mention the characterization of the electronic band structure of such graphene-TI junctions. The difficulty lies in the fact graphene can not be directly grown *in situ* on the surface of TIs such as Bi_2Se_3 and Sb_2Te_3 . In this work we report on an experimental route to preparing graphene- Sb_2Te_3 heterostructures in laboratory. We also perform angle-resolved photoemission (ARPES) measurements on the lab-prepared graphene-TI heterostructure and demonstrate the coexistence of two Dirac modes of different types. The results suggest a potential tunable electronic platform for studying the interaction between two different Dirac low-energy states.

The micro- and nano-ARPES experiments were carried out at the ANTARES beamline at the SOLEIL synchrotron [19–22] having respective lateral resolutions of $\sim 90 \mu\text{m}$ and $\sim 120 \text{ nm}$. The nanoARPES microscope is equipped with two Fresnel zone plates (FZP) to focalize the beam and an order selection aperture to eliminate higher diffraction orders. The sample was mounted on a nano-positioning stage, which was placed at the coincident focus point of the electron analyzer and the FZP. The conventional and nano-resolved photoelectron spectra were obtained

using a hemispherical analyzer Scienta R4000 with 5 meV and 0.005 \AA^{-1} , energy and momentum resolutions, respectively. The Scienta detector is aligned along the Γ -K direction of graphene. All photoemission measurements at ANTARES were done at a temperature of 100 K. The samples were degassed *in situ* at 200 °C for 8 hours before ARPES measurements. The degassing was proved to be critical for acquiring good ARPES spectra.

The first-principles calculations were based on the generalized gradient approximation (GGA)[23] using the full-potential projected augmented wave method[24] as implemented in the VASP package.[25] The electronic structure of bulk Sb_2Te_3 were calculated using a $15 \times 15 \times 6$ Monkhorst-Pack k -mesh over the Brillouin zone (BZ) with the spin-orbit coupling included self-consistently. The surface states were calculated from the surface Green's function of the semi-infinite system.[26] A $30 \times 30 \times 1$ Monkhorst-Pack k -mesh was used in the calculation for graphene.

We choose Sb_2Te_3 as the TI substrate because the lattice constant of the (111) surface of Sb_2Te_3 ($a = 4.26 \text{ \AA}$) matches nearly perfectly a $\sqrt{3} \times \sqrt{3}$ super cell of graphene ($a = 2.46 \text{ \AA}$). Therefore the heterostructure in the perfect alignment can be described by a commensurate $\sqrt{3} \times \sqrt{3}$ stacking pattern. Graphene/ Sb_2Te_3 heterostructures were prepared using a dry transfer of chemical vapor deposition (CVD) grown graphene film [27]. Graphene film was grown on Cu foils at ambient pressure which has been reported elsewhere [28–30]. Briefly, the growth was at 1065 °C with 20 sccm methane (500 ppm in Ar) and 200 sccm forming gas (5% H_2 in Ar) for 60-75 minutes. Prior to the growth, clean Cu foil was annealed for 120 minutes in the forming gas environment. The Sb_2Te_3 thin film was grown (at RTI International) on an undoped GaAs(100) substrate by metalorganic chemical vapor deposition (MOCVD) process. To transfer as-grown graphene film, a PMMA layer was spin-coated onto one side of the Cu foil, and the graphene on the opposite side of the Cu foil was removed by oxygen plasma. Next, a piece of wafer dicing tape (Blue Med Tack Squares from Semiconductor Equipment Corp.) with a small window cut in its center was adhered to the graphene covered with PMMA. The exposed Cu was then dissolved in ammonium persulfate solution ($\sim 2.5 \text{ g}$ in 50 ml DI water), obtaining a suspended PMMA/graphene membrane. After Cu etching, the sample was further cleaned by DI water and SC2 baths ($\text{HCl}:\text{H}_2\text{O}_2:\text{H}_2\text{O}=1:1:50 \text{ ml}$). The sample is subsequently rinsed by isopropanol and blown dry with N_2 gas. The typical domain size of graphene is about $20 \text{ }\mu\text{m}$. Finally, the suspended sample was transferred onto Sb_2Te_3 substrate, and followed by dissolving the PMMA layer in acetone. Figure 1(a) shows an optical micrograph of the surface of graphene/ Sb_2Te_3 (thickness of $\text{Sb}_2\text{Te}_3 = 1360 \text{ nm}$).

A Horiba Jobin Yvon XploRA confocal Raman system with a solid-state laser operating at a wavelength of 532 nm and a spectral resolution of 1.1 cm^{-1} was used for the Raman spectroscopy measurement. Power of the laser was maintained below 1 mW to minimize local heating effect. The laser spot size was $0.6 \text{ }\mu\text{m}$ in diameter with a $100\times$ objective ($\text{NA} = 0.90$) and all measurements were performed in an air ambient environment and at room temperature. As shown in Fig. 1(b), there are two high-frequency Raman modes at 1584 cm^{-1} and 2676 cm^{-1} in the Raman spectra, corresponding to the G and 2D modes of graphene [31]. We also observe a series of characteristic Raman modes at 73 cm^{-1} (A_{1g}^1), 113 cm^{-1} (E_g^2) and 166 cm^{-1} (A_{1g}^2) for Sb_2Te_3 [32]. Two extra peaks could be associated with surface oxidation of the Sb_2Te_3 thin film. The measured Raman characteristics confirm the success in fabricating graphene/ Sb_2Te_3 heterostructures.

The lattice structure of graphene/ Sb_2Te_3 with a perfect angle match is plotted in Fig. 1(c). In this case the surface unit cell of the heterostructure is same as that of Sb_2Te_3 . However, in reality, there is no epitaxial relationship between CVD graphene and Sb_2Te_3 and being van der Waals coupled they can be oriented in any angles. Figure 1(d) shows the photoemission spectrum taken with 700 eV photons. The characteristic core levels of C, Sb, and Te atoms are observed, indicating the correct chemical composition of the samples. We also notice in the spectrum there exist several extra peaks which can be attributed to the contamination introduced during the *ex situ* assembly of the heterostructure.

The Brillouin zone corresponding the stacking geometry in Fig. 1(c) is shown in Fig. 2(a). The K point of graphene (where the Dirac point of graphene is located) coincide with the $\bar{\Gamma}$ point of Sb_2Te_3 in the second zone. Under this ideal situation the Dirac cones of graphene and Sb_2Te_3 overlap in momentum space, and we can expect strong interaction between the Dirac states. In the nonideal case which there exists an angle mismatch, the Dirac cones of two materials separate in k space and the interaction between them is weaker. Therefore we have a tunable system (depending on the twist angle) for studying the correlation between two Dirac low-energy modes and the resulting novel transport behaviors. First-principles band structure of Sb_2Te_3 superimposed with that of graphene (green solid lines) is shown in Fig. 2(b). We can see the Dirac cone of graphene indeed overlap with the topological surface states of Sb_2Te_3 . Figure 2(c) presents ARPES mapping of a Sb_2Te_3 film employed as the substrate in our experiment (without *in situ* cleavage). The mapping at the Fermi level clearly resolve the Dirac point of the topological surface states and six lobes of bulk valence band as marked by arrows, indicating the good surface quality of the MOCVD-grown

Sb₂Te₃ film despite a brief exposure to the air (which is inevitable during the transfer of graphene). A comparison of the ARPES spectrum of Sb₂Te₃ with the calculated band structure is given in Fig. 2(d). We find a good consistency between the experimental and theoretical results: the Fermi level cuts the topological surface bands at the Dirac point and also grazes the top of the bulk valence band.

ARPES results taken from our graphene/Sb₂Te₃ sample is shown in Fig. 3(a). Comparing with the result from the bare Sb₂Te₃ surface, there are two additional bright spots in the ARPES mapping of the heterostructure, as indicated by the arrows. They are from the π band of graphene. The two spots indicate there are two major domains with different twist angles in the CVD graphene layer. The twisting geometry of the sample is illustrated in Figs. 3(b) and 3(c). According to the ARPES spectra, the distance between the Dirac band of graphene and the zone center is equal to the momentum of Sb₂Te₃ surface states in the second zone, which confirms the lattice constant match of the two Dirac materials. The twist angles of two graphene domains with respect to Sb₂Te₃ are 21° and 20°, respectively. To further show the energy dispersion of Dirac fermions in this heterostructure, we plot ARPES spectral cuts at different azimuthal angles (as marked by the dashed lines in the panel on the right hand side) in Fig. 4. At angles of 22°, 82°, and 142°, we observed the Dirac surface states of Sb₂Te₃. We note that the quality of the spectrum is worse than that reported in Fig. 2, which can be attributed to the coverage of graphene as well as the contamination introduced during the transfer of graphene. At 43° and 103° we saw the linear Dirac π band from one graphene domain. The π band of the other graphene domain was observed at 62° and 122°. Through fitting the Fermi velocity of CVD graphene is found to be $(1.01 \pm 0.12) \times 10^8 \text{ cm} \cdot \text{s}^{-1}$. In the spectral cuts only one branch of the graphene π band shows up, see Fig. 4. It is due to a well-known selection rule on photoexcitation matrix elements [9, 33]. The ARPES cuts confirm the twisting geometry schematic shown in Fig. 3(c) and the coexistence of two different Dirac modes in our graphene/Sb₂Te₃ samples, which is the key conclusion of this work.

In this work, we explored a practical approach to fabricating graphene/TI heterostructure, a promising platform for studying interacting Dirac fermions. Our ARPES experiment demonstrated the coexistence of the Dirac low-energy states of graphene and Sb₂Te₃ in our lab-prepare sample. A twist angle between the epitaxial graphene layer and the TI substrate was identified by our photoemission measurement. This twist angle provides a tunable degree of freedom for manipulating

the electronic properties of the heterojunction system. Our work presented a first step towards an ideal system of two interacting Dirac fermions with a tunable interaction strength. Further improvements on the sample preparation are desired: first, reduce the contamination introduced during the transfer of graphene; second, increase the domain size of graphene; and third, a precise way to control the twist angle. Those efforts will refine the graphene/TI system in such a way that could eventually enable the observation of the proximity effect on the graphene π band and potentially the quantum spin-Hall effect in the original Kane-Mele model of graphene.
